Assignment 1: CS 754, Advanced Image Processing

Due: 5th Feb before 11:55 pm

1. Let $\boldsymbol{\theta}^\star$ be the result of the following minimization problem (BP): $\min\|\boldsymbol{\theta}\|_1$ such that $\|\boldsymbol{y} - \boldsymbol{\Phi\Psi\theta}\|_2 \leq \varepsilon$, where $\boldsymbol{y}$ is an m-element measurement vector, $\boldsymbol{\Phi}$ is a $m \times n$ measurement matrix $(m < n)$, $\boldsymbol{\Psi}$ is a $n \times n$ orthonormal basis in which n-element signal $\boldsymbol{x}$ has a sparse representation of the form $\boldsymbol{x} = \boldsymbol{\Psi\theta}$. Notice that $\boldsymbol{y} = \boldsymbol{\Phi x} + \boldsymbol{\eta}$ and ε is an upper bound on the magnitude of the noise vector $\boldsymbol{\eta}$.

   Theorem 3 we studied in class states the following: If $\boldsymbol{\Phi}$ obeys the restricted isometry property with isometry constant $\delta_{2s} < \sqrt{2} - 1$, then we have $\|\boldsymbol{\theta} - \boldsymbol{\theta}^\star\|_2 \leq C_1 s^{-1/2}\|\boldsymbol{\theta} - \boldsymbol{\theta_s}\|_1 + C_2\varepsilon$ where C_1 and C_2 are functions of only δ_{2s} and where $\forall i \in \mathcal{S}, \boldsymbol{\theta_{si}} = \theta_i; \forall i \notin \mathcal{S}, \boldsymbol{\theta_{si}} = 0$. Here $\mathcal{S}$ is a set containing the s largest magnitude elements of $\boldsymbol{\theta}$.

   A curious student asks the following questions: '(1) It appears that the upper bound on $\|\boldsymbol{\theta} - \boldsymbol{\theta}^\star\|_2$ is reduced as s increases, which goes against the very premise of compressed sensing. How do we address this apparent discrepancy? (2) It also appears that the error bound is independent of m. How do you address this? (3) Now consider that I gave you another theorem (called Theorem 3A), which is the same as Theorem 3 except that it requires that $\delta_{2s} < 0.1$. Out of Theorem 3 and Theorem 3A, which is the more useful theorem? Why? (4) It appears that if I set $\varepsilon = 0$ in BP, I can always reduce the upper bound on the error even if the noise vector $\boldsymbol{\eta}$ has non-zero magnitude. What am I missing?'
   Your job is to answer all four of the student's questions. [5+5+5+5=20 points]
   Solution: (1) The error bound actually does not decrease. First of all, C_1, C_2 are monotonically increasing functions of δ_{2s}. As s increases, so does δ_{2s} and hence C_1, C_2 both increase. Moreover as s increases, the minimum number of measurements for the RIP to hold $(m \geq \mathcal{O}(s \log n))$, also increases. (2) The error bound is not independent of m. RIP for random matrices will typically require $m \geq \mathcal{O}(s \log n)$ measurements to guarantee reconstruction of s-sparse signals. (3) Theorem 3A is less powerful, as its guarantees hold for a smaller set of values of δ_{2s} (i.e. $\delta_{2s} < 0.1$) than Theorem 3 which requires $\delta_{2s} < 0.414$. (4) The error bounds for Theorem 3 are *conditional* on $\|\boldsymbol{y} - \boldsymbol{Ax}\|_2$ actually following below a sensible value of ε, provided based on the noise level. Setting ε to 0 would violate that condition and therefore the error bounds would no longer hold. In fact, the reconstruction would overfit to the noise.
   Marking scheme: No marks for guesswork. A convincing reason needs to be provided in all cases.

2. We will prove why the value of the coherence between $m \times n$ measurement matrix $\boldsymbol{\Phi}$ (with all rows normalized to unit magnitude) and $n \times n$ orthonormal representation matrix $\boldsymbol{\Psi}$ must lie within the range $[1, \sqrt{n}]$ (both 1 and $\sqrt{n}$ inclusive). Recall that the coherence is given by the formula
   $\mu(\boldsymbol{\Phi}, \boldsymbol{\Psi}) = \sqrt{n}\max_{i\in\{0,1,\ldots,m-1\},j\in\{0,1,\ldots,n-1\}}|\boldsymbol{\Phi^i\Psi_j}|$. Proving the upper bound should be very easy for you. To prove the lower bound, proceed as follows. Consider a unit vector $\boldsymbol{g} \in \mathbb{R}^n$. We know that it can be expressed as $\boldsymbol{g} = \sum_{k=1}^{n} \alpha_k\boldsymbol{\Psi_k}$ as $\boldsymbol{\Psi}$ is an orthonormal *basis*. Now prove that $\mu(\boldsymbol{g}, \boldsymbol{\Psi}) = \sqrt{n}\max_{i\in\{0,1,\ldots,n-1\}}\dfrac{|\alpha_i|}{\sum_{j=1}^{n}\alpha_j^2}$.
   Exploiting the fact that $\boldsymbol{g}$ is a unit vector, prove that the minimal value of coherence is attained when $\boldsymbol{g} = \sqrt{1/n}\sum_{k=1}^{n}\boldsymbol{\Psi_k}$ and that hence the minimal value of coherence is 1. [10 points]
   Solution: The upper bound is achieved when there exists a row of $\boldsymbol{\Phi}$ which is equal to (or the element-wise negative of) some column of $\boldsymbol{\Psi}$. This produces $\mu = \sqrt{n}$. As given in the question, we have $\mu(\boldsymbol{\Psi}, \boldsymbol{g}) = \max_{i\in\{0,1,\ldots,n-1\}}\dfrac{|\alpha_i|}{\sqrt{\sum_{j=1}^{n}\alpha_j^2}}$. As $\boldsymbol{g}$ is a unit vector and $\boldsymbol{\Psi}$ is orthonormal, we must have $\|\boldsymbol{g}\|_2^2 = \sum_{j=1}^{n}\alpha_j^2 = 1$.
   Hence $\mu(\boldsymbol{\Psi}, \boldsymbol{g}) = \max_{i\in\{0,1,\ldots,n-1\}}|\alpha_i|$, and we want the value of $\mu(\boldsymbol{\Psi}, \boldsymbol{g})$ to be the least possible. Thus $\mu^{min}(\boldsymbol{\Psi}, \boldsymbol{g}) = \sqrt{n}\text{argmin}_{\alpha_0,\alpha_1,\ldots,\alpha_{n-1}}\max_{i\in\{0,1,\ldots,n-1\}}|\alpha_i|$. Since $\sum_j \alpha_j^2 = 1$, the maximum value of $|\alpha_i|$ will be

the least when $\forall i, \forall j \neq i, |\alpha_i| = |\alpha_j|$, which happens when $\forall i, \alpha_i = \frac{\pm 1}{\sqrt{n}}$. This yields $\mu^{min}(\Psi, \mathbf{g}) = \sqrt{n} \left| \frac{\pm 1}{\sqrt{n}} \right| = 1$.

Marking scheme: 3 points for upper bound. 7 points for lower bound.

3. Compressive sensing reconstructions involve estimating a sparse signal $\mathbf{x} \in \mathbb{R}^n, n \gg 2$ from a vector $\mathbf{y} \in \mathbb{R}^m (m \ll n)$ of compressed measurements of the form $\mathbf{y} = \Phi \mathbf{x}$ where $\Phi \in \mathbb{R}^{m \times n}$ is the measurement matrix (assume there is no noise). Now answer the following questions, from first principles. **Do not merely quote theorems or algorithms.**

   (a) If it is known that $\mathbf{x}$ has only 1 non-zero element and that the other elements are zero, can you uniquely estimate $\mathbf{x}$ if $m = 1$? If yes, how? If not, why not? Now further suppose, you knew beforehand the index (but not the value) of the non-zero element of $\mathbf{x}$? Does this help you any further? If yes, how? If not, why not?

   (b) If it is known that $\mathbf{x}$ has only 1 non-zero element and that the other elements are zero, can you uniquely estimate $\mathbf{x}$ if $m = 2$? If yes, how? If not, why not?

   (c) If it is known that $\mathbf{x}$ has only 2 non-zero elements and that the other elements are zero, can you uniquely estimate $\mathbf{x}$ if $m = 3$? If yes, describe an algorithm that is guaranteed to estimate it accurately. If not, explain why not, and explain whether there are any special instances of Φ for which unique estimation is possible?

   (d) Repeat part (c) with $m = 4$. [1+2+3+4=10 points]

Solution: (a) You cannot estimate $\mathbf{x}$ if $m = 1$ because $\frac{y}{\Phi_j}$ could pass of as the non-zero value in $\mathbf{x}$ for any index $j \in \{1, 2, ..., n\}$. If you knew the index with the non-zero element (say k), then you can uniquely determine $\mathbf{x}$ as long $\Phi_k \neq 0$.

(b) In this case, we have $y_1 = \Phi_{1k} x_k$ and $y_2 = \Phi_{2k} x_k$. In this case, we can compute $\frac{y_1}{\Phi_{1j}}$ for all indices j and choose the one for which $y_2 = \Phi_{2j} \frac{y_1}{\Phi_{1j}}$. The solution is unique if no two columns of Φ are parallel to each other.

(c) In this case, we have $\begin{pmatrix} y_1 \\ y_2 \\ y_3 \end{pmatrix} = \begin{pmatrix} \Phi_{1j} & \Phi_{1k} \\ \Phi_{2j} & \Phi_{2k} \\ \Phi_{3j} & \Phi_{3k} \end{pmatrix} \begin{pmatrix} x_j \\ x_k \end{pmatrix}$. A unique solution can be obtained only if you knew j and k, the two non-zero indices. Otherwise a unique solution is not possible because to uniquely recover a 2-sparse vector, it is necessary and sufficient that any 4 columns of Φ be linearly independent (see proof for uniqueness of solution of problem P0 in the lecture slides). This is impossible because Φ has only 3 rows.

(d) In this case, a unique solution for the 2-sparse vector $\mathbf{x}$ may be obtained if Φ satisfies the requirement that any four of its columns must be linearly independent. This is easy to satisfy with high probability if Φ is picked randomly from a Gaussian or a Bernoulli distribution. A brute-force method of estimating $\mathbf{x}$ is to search over all column-subsets of Φ of size 4, and compute a putative solution for each by simple matrix inverse. The solution which is the sparsest is the one we want. Uniqueness of the solution is guaranteed by the assumption on Φ - see the lecture slides for proof of uniqueness of solution of problem P0. Another method: A brute-force method of estimating $\mathbf{x}$ is to (1) search over all column-subsets of Φ of size 2 to yield indices j_1, j_2 as the possible support of the 2-sparse vector $\mathbf{x}$, (2) compute a putative solution $\hat{\mathbf{x}}_{j_1, j_2}$ for each such pair j_1, j_2 by simple matrix inverse using any two measurements y_1, y_2, and (3) retain only that solution $\hat{\mathbf{x}}_{j_1, j_2}$ for which $y_3 = \Phi^3 \hat{\mathbf{x}}_{j_1, j_2}$ and $y_4 = \Phi^4 \hat{\mathbf{x}}_{j_1, j_2}$.

4. Consider compressive measurements of the form $\mathbf{y} = \mathbf{Ax} + \mathbf{v}$ for sensing matrix $\mathbf{A}$, signal vector $\mathbf{x}$, noise vector $\mathbf{v}$ and measurement vector $\mathbf{y}$. Consider the problem P1 done in class: Minimize $\|\mathbf{x}\|_1$ w.r.t. $\mathbf{x}$ such that $\|\mathbf{y} - \mathbf{Ax}\|_2 \leq e$. Also consider the problem Q1: Minimize $\|\mathbf{Ax} - \mathbf{y}\|_2$ w.r.t. $\mathbf{x}$ subject to the constraint $\|\mathbf{x}\|_1 \leq t$. Prove that if $\mathbf{x}$ is a unique minimizer of P1 for some value $e \geq 0$, then there exists some value $t \geq 0$ for which $\mathbf{x}$ is also a unique minimizer of Q1. Note that $\|\mathbf{x}\|_1$ and $\|\mathbf{x}\|_2$ stand for the L1 and L2 norms of the vector $\mathbf{x}$ respectively. [15 points] (Hint: Consider $t = \|\mathbf{x}\|_1$ and now consider another vector $\mathbf{z}$ with

L1 norm less than or equal to t).

Solution: Let $\boldsymbol{x}$ be the unique minimizer of P1, and we set $t = \|\boldsymbol{x}\|_1$. Now consider a vector $\boldsymbol{z} \neq \boldsymbol{x}$ such that $\|\boldsymbol{z}\|_1 \leq t$. As $\boldsymbol{x}$ is the *unique* minimizer of P1, this necessarily implies that $\boldsymbol{z}$ cannot obey the constraint $\|\boldsymbol{y} - \boldsymbol{A}\boldsymbol{z}\|_2 \leq e$. Hence we must have $\|\boldsymbol{y} - \boldsymbol{A}\boldsymbol{x}\|_2 \leq e < \|\boldsymbol{y} - \boldsymbol{A}\boldsymbol{z}\|_2$. This will hold true for any vector $\boldsymbol{z}$ with ℓ_1-norm less than or equal to t. This shows that $\boldsymbol{x}$ uniquely minimizes $\|\boldsymbol{y} - \boldsymbol{A}\boldsymbol{x}\|_2$ subject to the constraint that $\|\boldsymbol{x}\|_1 \leq t$.

Marking scheme: 15 points for the proof. Partial credit for a reasonable (even if incomplete) attempt.

5. Here is our mandatory Google search question. Note that this is the only question for which you can perform a google search to get the answer. Your task is to search for a research paper which applies compressed sensing in any one application not covered in class. Some examples include air quality monitoring, optical microscopy, or any other. Answer the following questions briefly:

   (a) Mention the title of the paper, where and when it was published, which venue (name of journal or conference or workshop) and include a link to the paper.

   (b) Very briefly describe the hardware architecture used in the paper. You may refer to figures from the paper itself.

   (c) What reconstruction techhnique or cost function does the paper adopt for the sake of compressive reconstruction in this application? [3+4+4=10 points]

   Solution: I will give one example, referring to `https://www.pnas.org/content/109/26/E1679`, 'Compressive fluorescence microscopy for biological and hyperspectral imaging'. The hardware architecture for biological imaging in the paper is very similar to the Rice single pixel camera. The sensing matrix is random binary and implemented via a DMD system. The representation matrix proposed is either wavelets of Fourier. The reconstruction technique is same as problem P1 (or the LASSO problem in equation 6 – a relaxed version of P1).
   Another example is one of my own recent papers on applying compressed sensing for correction of images of scenes submerged beneath a wavy water surface but imaged from a camera out in the air. The wavy water surface causes refractive distortions in every frame of the video. A LASSO formulation is used to compute the motion vector field between every frame and a certain mean image. The 'measurements' include trajectories of salient feature points tracked across the frames. The paper is Jerin Geo James, Pranay Agrawal and Ajit Rajwade, "Restoration of Non-rigidly Distorted Underwater Images using a Combination of Compressive Sensing and Local Polynomial Image Representations", International Conference on Computer Vision (ICCV) 2019.

6. In class, we studied a video compressive sensing architecture from the paper 'Video from a single exposure coded snapshot' published in ICCV 2011 (See `http://www.cs.columbia.edu/CAVE/projects/single_shot_video/`). Such a video camera acquires a 'coded snapshot' E_u in a single exposure time interval u. This coded snapshot is the superposition of the form $E_u = \sum_{t=1}^{T} C_t \cdot F_t$ where F_t is the image of the scene at instant t within the interval u and C_t is a randomly generated binary code at that time instant, which modulates F_t. Note that E_u, F_t and C_t are all 2D arrays. Also, the binary code generation as well as the final summation all occur within the hardware of the camera. Your task here is as follows:

   (a) Read the 'cars' video in the homework folder in MATLAB using the 'mmread' function which has been provided in the homework folder and convert it to grayscale. Extract the first $T = 3$ frames of the video.

   (b) Generate a $H \times W \times T$ random code pattern whose elements lie in $\{0, 1\}$. Compute a coded snapshot using the formula mentioned and add zero mean Gaussian random noise of standard deviation 2 to it. Display the coded snapshot in your report.

   (c) Given the coded snapshot and assuming full knowledge of C_t for all t from 1 to T, your task is to estimate the original video sequence F_t. For this you should rewrite the aforementioned equation in the form $\boldsymbol{A}\boldsymbol{x} = \boldsymbol{b}$ where $\boldsymbol{x}$ is an unknown vector (vectorized form of the video sequence). Mention clearly what $\boldsymbol{A}$ and $\boldsymbol{b}$ are, in your report.

(d) You should perform the reconstruction using Orthogonal Matching Pursuit (OMP). For computational efficiency, we will do this reconstruction patchwise. Write an equation of the form $Ax = b$ where x represents the ith patch from the video and having size (say) $8 \times 8 \times T$ and mention in your report what A and b stand for. For perform the reconstruction, assume that each 8×8 slice in the patch is sparse or compressible in the 2D-DCT basis. Carefully work out the error term in the OMP algorithm, and explain this in your report!

(e) Repeat the reconstruction for all overlapping patches and average across the overlapping pixels to yield the final reconstruction. Display the reconstruction and mention the relative mean squared error between reconstructed and original data, in your report as well as in the code.

(f) Repeat this exercise for $T = 5, T = 7$ and mention the mention the relative mean squared error between reconstructed and original data again.

(g) **Note: To save time, extract a portion of about 120×240 around the lowermost car in the cars video and work entirely with it. In fact, you can show all your results just on this part. Some sample results are included in the homework folder.**

(h) Repeat the experiment with any consecutive 5 frames of the 'flame' video from the homework folder. [35 points = 18 points for successful OMP implementation + 7 points for carefully presenting error term bound + 10 points for displaying of all results]

Solution and Marking scheme: The values of a Gaussian random variable with mean 0 and standard deviation σ lie in the range $[-3\sigma, +3\sigma]$ with 0.99 probability. Hence a reasonable bound for the error for OMP would be $\|b - Ax\|_2^2 \leq 3m\sigma^2$ for m measurements. A more rigorous treatment would involve tail bounds of the chi-square distribution with m degrees of freedom. We would have $P(\|b - Ax\|_2^2 \leq \sigma^2(m + 2m(\sqrt{t} + t))) \geq 1 - \exp(-tm)$. See `https://math.stackexchange.com/questions/2864188/chi-squared-distribution-tail-bound` and references therein.

The first solution with $3\sigma^2$ is less rigorous but acceptable and will be awarded full 7 marks. For a basic working OMP which is stub-tested on simple matrices, we will award 9 points out of 18. The remaining 9 are for correct implementation on *this* particular video CS problem. 10 points for display of appropriate results. For every result not displayed in the report, 2 points will be deducted. If the result is displayed in the code, but not the report, only 1 point will be deducted. For the flame video, the five consecutive frames should show *some* motion, otherwise two points are to be deducted.
